Efficient energy conversion and storage is crucial for development of systems based on renewable energy sources. For electricity storage, Li-ion batteries are commonly used in electronics devices but require many improvements to obtain longer life-time and higher energy densities. The current use of organic liquids and gels electrolytes limits these improvements because of lithium dendrites formation, reducing the lifetime of the battery and which can possibly be hazardous due to risks of short circuits.

An alternative to current state-of-art lithium-ion batteries could be solid-state batteries of higher stability and no risks of electrolyte leakage. LiBH₄ is a promising material for solid-state batteries as it is lightweight and stable electrochemically up to 5 V. Similar to other metal borohydrides, LiBH₄ exists in different polymorphs. While the orthorhombic phase (*Pnma*), stable at room temperature has a low ionic conductivity ($\sim 10^{-5}$ mS cm⁻¹ at 30 °C), the hexagonal phase (*P63/mmc*), stable above 110 °C, has a much higher ionic conductivity (~ 1 mS cm⁻¹ at 120 °C) [1]. Confinement of LiBH₄ in mesoporous SiO₂ allows obtaining fast ionic conductivity even at room temperature. Figure 1 shows Arrhenius plot of ionic conductivities of bulk LiBH₄ and nanoconfined SiO₂. For LiBH₄ the clear increase of the conductivity at 110 °C is due to the phase transition.

The origin of the high ionic conductivity in the nanoconfined LiBH₄ is due to an interfacial layer created between the borohydride and the walls of the SiO₂ pores. Better knowledge of the mechanisms behind the formation of this interface as well as the effect of the mesoporous SiO₂ structure parameters (pore size, surface area,...) are crucial for improving even further the ionic conductivity of the low temperature solid electrolytes to be use in solid-sate lithium ion batteries.
